## Understanding the Data

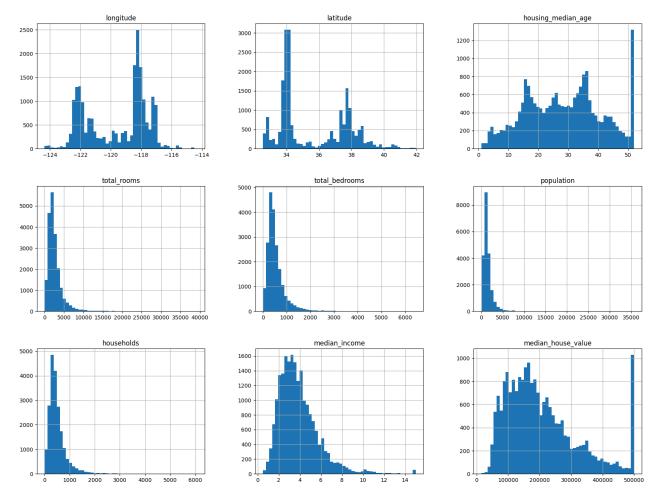

```
In [ ]: import os
        import tarfile
        from six.moves import urllib
        import pandas as pd
        DOWNLOAD_ROOT = "https://raw.githubusercontent.com/ageron/handson-ml2/master/"
        HOUSING_PATH = os.path.join("datasets", "housing")
        HOUSING_URL = DOWNLOAD_ROOT + "datasets/housing/housing.tgz"
        def fetch_housing_data(housing_url=HOUSING_URL, housing_path=HOUSING_PATH):
            if not os.path.isdir(housing path):
                os.makedirs(housing path)
            tgz_path = os.path.join(housing_path, "housing.tgz")
            urllib.request.urlretrieve(housing_url, tgz_path)
            housing_tgz = tarfile.open(tgz_path)
            housing_tgz.extractall(path=housing_path)
            housing tgz.close()
        upon calling the function fetch_housing_data(), it
```

- 1. creates datasets/housing directory
- 2. downloads housing.tgz
- 3. extracts housing.csv in the directory

         Name: median_income, Length: 20640, dtype: float64
```

You find out that the median\_income is represented in ten thousands of US dollars. eg: 8 means \$80,000

#### Making a Test Set and Training Set

```
In []: # creating a test set (generally 20% of the dataset or even less if dataset is too large)

import numpy as np

def split_train_test(data, test_ratio):
    shuffled_indices = np.random.permutation(len(data))
    test_set_size = int(len(data) * test_ratio)
    test_indices, train_indices = shuffled_indices[:test_set_size], shuffled_indices[test_set_size:
```

Out[

```
return data.iloc[test_indices], data.iloc[train_indices]

test_set, train_set = split_train_test(housing, 0.2)
test_set.head()
```

]:		longitude	latitude	housing_median_age	total_rooms	total_bedrooms	population	households	median_i

	16915	-122.35	37.56	52.0	1659.0	191.0	519.0	201.0	
	4								•

#### Break-proofing the split approach

The next time the code is run again, it will choose different set of indices, over time, the model will get to see the whole dataset which is to be avoided.

#### Solutions:

- 1. Save test set on first run and load it in subsequent runs
- 2. Set a random number generator's seed before calling permutation() so it generates same shuffled indices

But both the solutions will break when fetching an updated dataset.

```
In []: # Best solution

from zlib import crc32

def test_set_check(identifier, test_ratio):
    return crc32(np.int64(identifier)) & 0xfffffffff < test_ratio * 2 ** 32

def split_train_test_by_id(data, test_ratio, id_column_name):
    ids = data[id_column_name]
    in_test_set = ids.apply(lambda id_: test_set_check(id_, test_ratio))
    return data.loc[~in_test_set], data.loc[in_test_set]</pre>
```

## Working of the test\_set\_check

- 1. the identifier is converted into a 64-bit integer.
- 2. The crc32 function returns the hash of the 64-bit identifier and it is masked with the highest value of 32 bit integer which is 0xffffffff to truncate it into a 32-bit integer.
- 3. the test\_ratio is multiplied with  $2^{32}$  to maintain the scale.
- 4. The hash is checked with the test\_ratio

```
In [ ]: # Add a custom ID column to the dataset since it does not have it
housing
```

# **Avoiding Sampling Bias**

It is important for a model to consider each and every category of an attribute to avoid sampling bias. for example, a survey on population of a country consisting of 55% males and 45% females need to take into consideration of 55 males and 45 females in a 100 people. If the percentages does not represent the whole population of the country, then the survey may be considered as biased.

Suppose the experts told you that the median income is a very important attribute to predict median housing prices. You should ensure that the test set is representative of the various categories of incomes in the whole dataset.

```
In []: plt = __import__("matplotlib").pyplot # using matplotlib's pyplot
In []: housing["median_income"].hist(figsize=(5, 5), bins=50)
    plt.show()
```

       5: 32.64812575574365%
       1: 11.349110381758507%
In [ ]: # percentage of categories in test set
        highest = max([j for _,j in strat_test_set["income_cat"].value_counts().items()])
        for i,j in strat_test_set["income_cat"].value_counts().items():
            print(str(i) + ":", str((j/highest)*100) + "%")
      3: 100.0%
       2: 90.94678645473392%
       4: 50.310988251554946%
       5: 32.61921216309606%
       1: 11.402902557014514%
```

Since both the train set and test set have the same number of categories shuffled randomly, the likelyhood of a Sampling Bias is significantly reduced.

You should remove the income\_cat attribute so the data is back to its original state.

#### Visualize the Data

The goal is to go a little more in-depth into understanding of the data. First, make sure the test-set is left aside and only the training set is explored.

<u>Note:</u> If the training set is very large, you may want to sample an exploration set, to make manipulations easy and fast. In this case, the training set is fairly small so you can directly work on the full set.

```
In []: # Plotting latitudes and longitudes to see the location of all districts
housing.plot(kind="scatter", x="longitude", y="latitude")
plt.show()
```

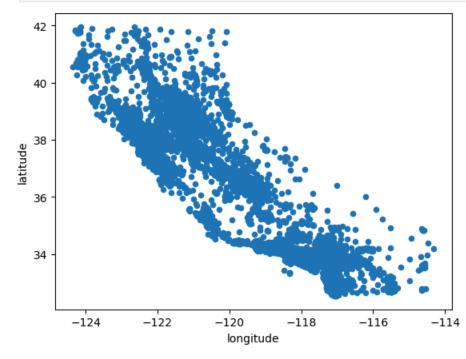

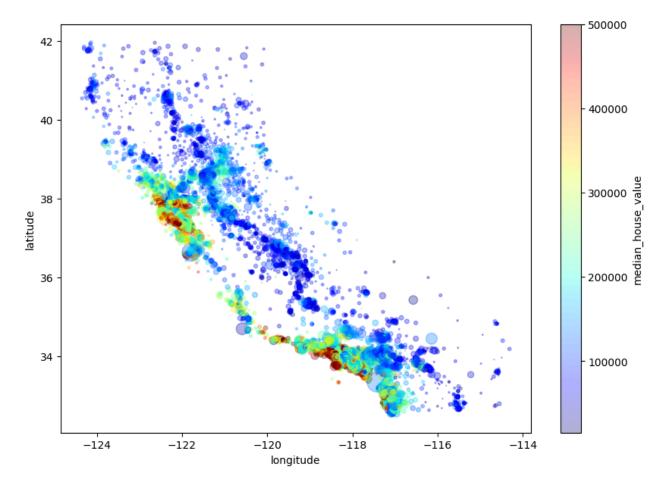

fig: scattered districts of California

highly densed areas can now be seen clearly.

Now let's visualize the population of each district in the state. The radius of the circles represents the district's population and the color represents the price (blue meaning more affordable and red being more expensive).

longitude

```
In []: housing.plot(
    kind="scatter",
    alpha=0.3,
    x="longitude",
    y="latitude",
    s=housing["population"]/100,
    c="median_house_value",
    cmap=plt.get_cmap("jet"),
    colorbar=True,
    figsize=(10,7)
)
plt.show()
```

Takeaways from the graph:

- 1. The housing prices are related to the location(eg, close to the ocean)
- 2. The housing prices are related to population density

### **Looking for Correlations**

We can compute the standard correlation coefficient between every pair of attributes using the corr() method.

```
In [ ]: # housing numeric only = housing.select dtypes(include=[np.number])
        # corr matrix = housing numeric only.corr()
        # corr matrix["median house value"].sort values(ascending=False)
        # (or)
        corr_matrix = housing.corr(numeric_only=True)
        corr_matrix["median_house_value"].sort_values(ascending=False)
Out[]: median house value
                               1.000000
        median income
                               0.688075
        total_rooms
                               0.134153
        housing_median_age
                              0.105623
        households
                               0.065843
        total bedrooms
                               0.049686
        population
                              -0.024650
        longitude
                              -0.045967
        latitude
                              -0.144160
        Name: median_house_value, dtype: float64
```

These correlations co-efficients are with respect the the <a href="median\_house\_value">median\_house\_value</a>. For example, the <a href="median\_house\_value">median\_house\_value</a> tends to go up when the <a href="median\_income">median\_income</a> goes up, because the correlation coefficient between the two is 0.688, which is pretty close to 1 and has a strong positive correlation.

Also, the median\_house\_value tends to go a little up the more you travel to the south because of the negative correlation between median house value and latitude.

Another way is to use <code>pandas.plotting.scatter\_matrix</code> function, which plots every numerical attribute against every other numerical attribute. This results in  $11^2$  = 121 correlations and 121 plots which won't fit in the graph. So we will only focus on a few promising attributes that seem most correlated with the <code>median\_house\_value</code> .

```
In [ ]: from pandas.plotting import scatter matrix
          attributes = ["median_house_value", "median_income", "total_rooms", "housing_median_age"]
            = scatter_matrix(housing[attributes], figsize=(12, 8))
          plt.show()
        median_house_value
           400000
           200000
               15
            median income
               10
            30000
          total_rooms
            20000
            10000
            housing_median_age
               40
                                                        median_income
                                                                                                                  housing_median_age
                                                                                        total rooms
                        median_house_value
```

Since the most useful attribute is the median income attribute, we will focus on that.

```
In []: housing.plot(kind="scatter", x="median_income", y="median_house_value", alpha=0.1, figsize=(8,4))
plt.show()
```
